Abstract

A search is conducted for new physics in final states containing a photon and missing transverse momentum in proton-proton collisions at $\sqrt{s} = 13$ TeV. The data collected by the CMS experiment at the CERN LHC correspond to an integrated luminosity of 35.9 inverse femtobarns. No deviations from the predictions of the standard model are observed. The results are interpreted in the context of dark matter production and limits on new physics parameters are calculated at 95% confidence level. For the two simplified dark matter production models considered, the observed (expected) lower limits on the mediator masses are both 950 (1150) GeV for 1 GeV dark matter mass.

Chapter 1

The CMS Detector

The Compact Muon Solenoid (CMS) detector is one of two hermetic, general purpose detectors at the Large Hadron Collider. The original motivation for the experiment was the discovery of the Higgs boson by observing its decays to photons, electrons, and muons. Towards this end, the detector was built to fulfill the following goals:

- Unambiguous charge identification of muons with momenta up to 1 TeV
- 1 GeV mass resolution on 100 GeV pairs of muons, electrons, and photons
- Efficient triggering and tagging of τ lepton and b quark decays
- Good resolution on the hadronic energy and missing transverse energy
- Sufficient time resolution to deal with 40 MHz of collisions

The CMS detector consists of four main subdetectors: the inner tracker system, the electromagnetic calorimeter (ECAL), the hadronic calorimeter (HCAL), and the muon chambers. The first three are within the field volume of the eponymous 3.8 T superconducting NbTi solenoid magnet while the muon chambers are embedded in the return yoke of the magnet. Additionally, there is an online triggering system to reduce readout from 40 MHz to $\mathcal{O}(1)$ kHz for prompt reconstruction.

The overall layout of the CMS detector is shown in Figure 1-1. The CMS detector has a weight of 12500 tons, a length of 22 m, a diameter of 15 m, and a cylindrical

geometry with concentric barrel shaped detectors in the central region and disc shaped detectors in the forward region. The following coordinate system is used when working with the CMS detector:

- distance z along the beam axis
 - $z = 0$ at the center of the detector
 - positive corresponds to counter-clockwise as seen from the sky
- distance r from the beam axis
- polar angle θ measured with respects to the positive z -axis
- azimuthal angle ϕ in the plane orthogonal to the beam axis

In addition to these four main coordinates, we define the right-handed cartesian x and y coordinates perpendicular to the beam axis, with the positive x -axis pointing

from the center of the detector to the center of the LHC ring and the positive y -axis pointing upwards.

The four-momentum of a particle is $p = (p_x, p_y, p_z, E)$ in the cartesian basis and a particle of mass m produced at rest in the center of the detector has $p = (0, 0, 0, m)$. While the momenta along the beam axis of the two incoming protons are equal, the momenta of the incoming partons involved in the hard scattering often are not as discussed in Section ???. Thus, we define two kinematic quantities that are Lorentz-invariant with respect to a boost along the beam axis: the transverse momentum $\vec{p}_T = p_x \hat{x} + p_y \hat{y}$ with magnitude $p_T = \sqrt{p_x^2 + p_y^2}$ and the pseudorapidity $\eta = -\ln \tan \theta/2$.

In terms of p_T , η , and ϕ , we have the following expressions for our cartesian variables: $p_x = p_T \cos \phi$, $p_y = p_T \sin \phi$, $p_z = p_T \sinh \eta$, and $E = p_T \cosh \eta$, with the last equality assuming the mass of the particle is negligible compared to its momentum. In terms of our Lorentz-invariant coordinates, the four-momentum of a given particle is $p = (p_T, \eta, \phi, E)$. Additionally, the spatial separation of two particles is given by $\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2}$ and the fiducial acceptance of the CMS detector is from $0 \leq \phi < 2\pi$ and $-5 \leq \eta \leq 5$.

1.1 Inner Tracker System

Closest to the interaction point, the inner tracker system identifies charged particles and measures their momenta. Additionally, high resolution tracks are used to identify primary and secondary vertices. The magnetic field in the tracker volume is uniform with strength 3.8 T and field lines parallel to the beam direction. The tracker volume extends to 1.2 m in r and 2.9 m in z , providing coverage for $|\eta| < 2.5$, and is instrumented with silicon pixels and strips. Each silicon sensor is a p - n semiconductor junction with a bias voltage applied. When a charged particle passes through the depletion region of the junction, electron-hole pairs are produced and collected by the readout electronics. A schematic of the inner tracker system is shown in Figure 1-2.

The 66 million individual pixel sensors, each measuring $285 \mu\text{m} \times 100 \mu\text{m} \times 150 \mu\text{m}$ in $r \times r\phi \times z$, are arranged into seven layers: three cylindrical barrels at $r =$

Figure 1-2: A schematic view of the CMS inner tracker system. Silicon pixel and strip detectors are shown. The volumes labeled TIB, TID, TOB, and TEC are all strip trackers. The double lines indicate back-to-back modules that deliver stereo hits. Reprinted from Reference [1].

4.4, 7.3, 10.2 cm and two bi-layer endcap annuli at $z = \pm 34.5, \pm 46.5$ cm. Due to the geometry of the pixel detector, tracks typically cross the sensor at a 20° angle, leading to the charge deposit from a single track to be shared among multiple pixels in the same layer. The exact position of a particle in each layer is determined by interpolating the signals from multiple adjacent pixels with an analog pulse height greater than a tuneable read-out threshold. Thus, each pixel hit is localized to an area of $\sim 15 \mu\text{m} \times 20 \mu\text{m}$ in $r\phi \times z$, providing a much higher spacial resolution than the raw pixel spacing.

The pixels are surrounded 9.3 million silicon strips measuring $10 \text{ cm} \times 80 \mu\text{m}$ arranged in ten cylindrical layers in the barrel and twelve disks in each endcap. The Tracker Inner Barrel (TIB) consists of the first four layers and extends from 20 cm to 55 cm in the radial direction while out six layers constitute the Tracker Outer Barrel (TOB) with an outer radius of 116 cm and extent in $|z|$ of 118 cm. The remaining area in the barrel is covered by the Tracker Inner Disk (TID), consisting of the three disks located from 80 to 90 cm in $|z|$. The Tracker EndCaps (TEC) have nine disks each and cover the region $124 \text{ cm} < |z| < 282 \text{ cm}$.

The majority of the strips are oriented perpendicular to the ϕ direction: parallel to the beam pipe in the barrel region and radially aligned in the endcap region. The strip pitch varies from 80 to $184\,\mu\text{m}$ with the smallest pitch in the innermost layer. This detector geometry provides good resolution in the r - ϕ plane for barrel and the z - ϕ plane for the endcap but little information on the orthogonal directions. To compensate for this, one third of the strips are double-layered with a stereo angle of 100 mrad between the layers. Matching hits between adjacent layers enables a measurement of the z and r coordinates in the barrel and endcap, respectively. The final spacial resolution is 10-50 μm in the direction perpendicular to the strips and 100-530 μm in the parallel direction on the stereo modules.

1.2 Electromagnetic Calorimeter

The electromagnetic calorimeter (ECAL) is a homogeneous, hermetic calorimeter composed of 76,000 lead tungstate (PbWO_4) crystals. High density ($8.3\,\text{g}/\text{cm}^3$) lead tungstate was chosen due to its radiation hardness, fast scintillation decay time constant of 25 ns, small Moliere radius $r_M = 21.9\,\text{mm}$, and short radiation length $X_0 = 8.9\,\text{mm}$. All of these factors combine to enable the construction of a compact calorimeter with high granularity and excellent energy resolution.

Figure 1-3 shows the layout of the ECAL. The central barrel region (EB) has 61200 crystals arranged in a 170×360 η - ϕ grid (0.0174×0.0174 granularity) with a coverage up to $|\eta| = 1.44$ while the two endcap annuli (EE) each have 7324 crystals organized in a x - y grid with coverage in the range $1.479 < |\eta| < 3.0$. Each crystal in the EB has a truncated pyramidal shape with a length of 230 mm, a $22\,\text{mm} \times 22\,\text{mm}$ front-face cross-section, and a $26\,\text{mm} \times 26\,\text{mm}$ rear-face cross-section while a crystal in the EE has a cuboid-like shape with a length of 220 mm, a $28.6\,\text{mm} \times 28.6\,\text{mm}$ front-face cross-section, and a $30\,\text{mm} \times 30\,\text{mm}$ rear-face cross-section. The cross-sectional area of approximately one Moliere radius and length of approximately 25 radiation lengths allows just a few crystals to contain the entire transverse and longitudinal development of the shower. To reduce the likelihood of the primary photon or electron

emerging from the hard scattering depositing most of its energy in passive material, the crystals do not point directly to the interaction region.

The interactions between the 3.8 T magnetic field and the geometries of the ECAL lead to the selection of different photosensors in the barrel and endcaps. In the endcaps, the magnetic field is parallel to the path of the photoelectrons and has a negligible effect on the gain, while in the barrel, the magnetic field is perpendicular and reduces the gain by a factor proportional to the distance traveled by the photoelectrons. Thus, in the barrel, solid-state reverse-structure avalanche photodiodes (APDs) with a depletion layer of $6.0 \pm 0.5 \mu\text{m}$ are used, while photomultiplier tubes with a single gain stage and a very fine copper mesh anode called vacuum phototriodes (VPTs) are used in the endcaps. Two APDs with an active area of 25 mm^2 are glued to the rear of each crystal in the barrel while only one VPT with an active area of 280 mm^2 is needed per crystal in the endcap. The APDs and VPTs amplify the initial signal of approximately 4.5 photoelectrons per MeV of energy deposit per

crystal by a factor of 50 and 10, respectively.

The small signals from the photodetectors are shaped and amplified in the Multi-Gain Preamplifier (MGPA) and a 12-bit analog-to-digital converter (ADC) samples the pulse every 25 ns. Each output voltage pulse has a length of approximately 300 ns, with the maximum at approximately 75 ns and a slow decay afterwards. The MGPA has multiple gain modes of 12, 6, and 1, and the gain chosen for the output decreases once the signal has saturated the previous gain setting. After the pulse falls below the saturation threshold, the lower gain setting is maintained for the next five samples. This mechanism provides a dynamic signal range from a few MeV to a maximum of 1.5 TeV in the barrel and 3.1 TeV in the endcaps.

The energy resolution of the ECAL was measured using an electron beam to be

$$\frac{\sigma_E}{E} = \frac{2.8\%}{\sqrt{E/\text{GeV}}} \oplus \frac{12\%}{E/\text{GeV}} \oplus 0.3\%, \quad (1.1)$$

where E is the energy of the incident particle and the three terms on the RHS are the stochastic, noise, and constant terms, respectively. The stochastic term is dominated by event-to-event fluctuations in the lateral shower containment and a photo-statistics contribution of 2.1%. Electronic and digitization noise drive the noise term while the constant term comes from a non-uniform longitudinal light collection and intercalibration errors.

1.2.1 Preshower Detector

At high momenta and high $|\eta|$, the two photons from a π^0 decay can merge into a single ECAL crystal due to the large boost in the z -direction of the initial state. By forcing the initiation of an electromagnetic shower in a region with high spacial resolution in front of the ECAL endcaps, the preshower detector can differentiate between one- and two-photon deposits in the region $1.6 < |\eta| < 2.5$. The preshower detector consists of two alternating layers of passive lead absorbers and active silicon strip sensors. The first (second) lead layer is two (one) radiation lengths thick and the subsequent sensor plane has vertical (horizontal) strips of 6 cm length and 1.9 mm

pitch. The silicon strips resolve the shower with a resolution of $\mathcal{O}(1-10)$ mm, enabling the disambiguation of two nearly collinear photons and the identification of π^0 decays.

1.3 Hadronic Calorimeter

The hadronic calorimeter (HCAL) is a set of four heterogeneous calorimeters that provide hermetic coverage when combined: the barrel calorimeter (HB) covering $|\eta| < 1.3$, the endcap calorimeter (HE) covering $1.3 < |\eta| < 3$, the outer calorimeter (HO) covering $|\eta| < 1.3$, and the forward calorimeter (HF) covering $3 < |\eta| < 5$. The region covering $|\eta| < 3$ shall be referred to as the central HCAL. The layout of the HCAL is shown in Figure 1-4.

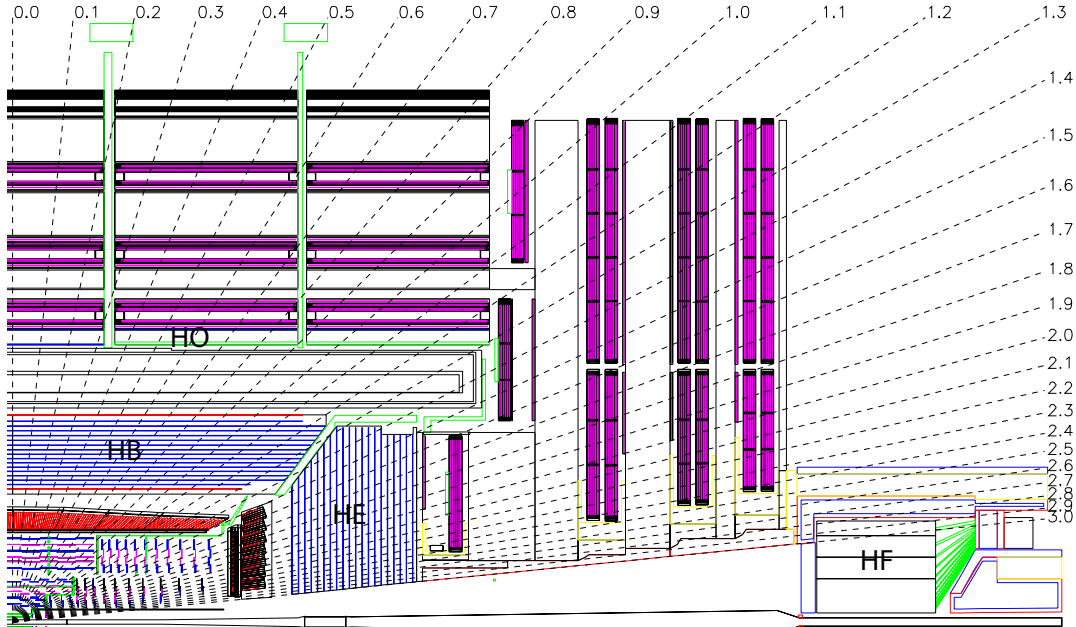

Figure 1-4: The layout of the CMS hadronic calorimeter. The barrel, endcap, outer, and forward calorimeters are shown and labeled. The muon chambers are shown but not labeled. The dashed lines denote different values of pseudorapidity. Reprinted from Reference [1].

The granularity of the central HCAL is 0.087×0.087 in η - ϕ for $|\eta| < 1.6$ and 0.17×0.17 for $1.6 < |\eta| < 3.0$. The HB (HE) consists of 16 (17) thin plastic scintillator

layers interleaved with thick absorber layers made of a non-magnetic brass alloy with an interaction length $\lambda_I = 1.5$ cm. The layers range in thickness from 40 to 75 mm providing a total absorber depth ranging from a minimum of $5.82 \lambda_I$ at $|\eta| = 0$ to a maximum of $10.6 \lambda_I$ at $|\eta| = 1.3$ in the barrel and approximately nine interaction lengths throughout the endcaps, with the ECAL contributing another interaction length worth of material. The dimensions of the HB and HE are determined by the requirement that they reside between the ECAL and the solenoid. To circumvent this constraint, an additional layer of scintillator located in the return yoke of the magnet, the HO, utilizes the solenoid material as an additional interaction length of absorber. Hybrid photodiodes (HPDs) are used to read out the scintillator light in the HB and HE while silicon photomultipliers (SiPMs) are used in the HO.
