Abstract

A search is conducted for new physics in final states containing a photon and missing transverse momentum in proton-proton collisions at $\sqrt{s} = 13$ TeV. The data collected by the CMS experiment at the CERN LHC correspond to an integrated luminosity of 35.9 inverse femtobarns. No deviations from the predictions of the standard model are observed. The results are interpreted in the context of dark matter production and limits on new physics parameters are calculated at 95% confidence level. For the two simplified dark matter production models considered, the observed (expected) lower limits on the mediator masses are both 950 (1150) GeV for 1 GeV dark matter mass.

Chapter 1

Motivation

1.1 The Standard Model

The Standard Model (SM) of particle physics describes the physical properties and dynamics of fermions, the fundamental constituents of matter, and their interactions in the language of a Lorentz-invariant quantum field theory (QFT). The Standard Model consists of a set of fermion fields, shown in Table 1.1 and the local gauge symmetry group that acts on them

$$G_{\text{SM}} = \text{SU}(3)_C \times \text{SU}(2)_L \times \text{U}(1)_Y, \quad (1.1)$$

which is composed of the subgroups

$$\begin{aligned} G_{\text{QCD}} &= \text{SU}(3)_C & \text{and} \\ G_{\text{EWK}} &= \text{SU}(2)_L \times \text{U}(1)_Y, \end{aligned} \quad (1.2)$$

corresponding to the strong and electroweak interactions, respectively. Each fermion field exists in a unique representation of G_{SM} , also summarized in Table 1.1. The possible representations of $\text{SU}(3)_C$ are triplet, conjugate, and singlet, denoted by $\mathbf{3}$, $\bar{\mathbf{3}}$, and $\mathbf{1}$, respectively, while the possible representations of $\text{SU}(2)_L$ are doublet and singlet, denoted by $\mathbf{2}$ and $\mathbf{1}$, respectively. All fermions exist in the singlet represen-

tation of $U(1)_Y$, only distinguished by differing values of the weak hypercharge Y . Conversely, all fermions in non-singlet representations of $SU(3)_C$ and $SU(2)_L$ have the same interaction strength, a feature known as universality.

Table 1.1: The categories of SM fermions and the action of the SM local gauge symmetry group G_{SM} . Each category contains three members, one for each generation of the Standard Model. A corresponding table exists for the charge conjugated fields representing the anti-fermions. The subscripts L and R denote whether the field is left- or right-handed.

| Name | Symbol | Y | $SU(2)_L$ rep. | $SU(3)_C$ rep. |
|------------------------------|----------|--------|----------------|----------------|
| Left-handed quark | q_L | $1/6$ | 2 | 3 |
| Right-handed up-type quark | u_R | $2/3$ | 1 | 3 |
| Right-handed down-type quark | d_R | $-1/3$ | 1 | 3 |
| Left-handed lepton | ℓ_L | $-1/2$ | 2 | 1 |
| Right-handed charged lepton | e_R | -1 | 1 | 1 |
| Right-handed neutrino | ν_R | $1/6$ | 1 | 1 |

For each category of fermion listed in Table 1.1, there exist three generations or copies in the Standard Model, identical except for differing masses. The lepton electroweak doublets contain the left-handed charged leptons and neutrinos

$$\ell_L = \begin{pmatrix} \nu_e \\ e_L^- \end{pmatrix}, \begin{pmatrix} \nu_\mu \\ \mu_L^- \end{pmatrix}, \begin{pmatrix} \nu_\tau \\ \tau_L^- \end{pmatrix}, \quad (1.3)$$

and the right-handed lepton singlets contain the right-handed projections of the same leptons and neutrinos. The quark electroweak doublets contain the left-handed up-type and down-type quarks

$$q_L = \begin{pmatrix} u_L \\ d_L \end{pmatrix}, \begin{pmatrix} c_L \\ s_L \end{pmatrix}, \begin{pmatrix} t_L \\ b_L \end{pmatrix}, \quad (1.4)$$

and the right-handed quark singlets contain the right-handed projections of the same quarks. Quarks also exist in a strong triplet, which will be denoted with a superscript c as necessary.

1.1.1 Strong Interactions

The strong interactions of quarks and gluons are described by quantum chromodynamics (QCD), with the Lagrangian

$$\mathcal{L}_{\text{QCD}} = i\bar{q}_f^a \not{D}^{ab} q_f^b + m_f \bar{q}_f^a q_f^a - \frac{1}{4} G_{\mu\nu}^a G^{a,\mu\nu} + \theta \frac{g_s^2}{72\pi^2} \epsilon_{\mu\nu\rho\sigma} G^{c,\mu\nu} G^{c,\rho\sigma}, \quad (1.5)$$

where repeated indices are contracted. The q_f^a are the quark-field Dirac spinors of flavor $f \in \{u, d, c, s, t, b\}$, color $a \in \{r, g, b\}$ (the basis element of the triplet representation), and mass m_f . The first term in Equation 1.5 contains the QCD covariant derivative

$$D_\mu^{ab} = \delta^{ab} \partial_\mu - ig_s \sum_c t_c^{ab} G_{c,\mu}, \quad (1.6)$$

where g_s is the strong interaction coupling strength, t_c are the eight 3×3 Hermitian traceless matrices that serve as the generators of the triplet representation of $\text{SU}(3)_C$, and G_c are the corresponding eight gluon fields. The third term in Equation 1.5 contains the gluon field strength tensors

$$G_{\mu\nu}^a = \partial_\mu G_\nu^a - \partial_\nu G_\mu^a - g_s f^{abc} G_\mu^b G_\nu^c, \quad (1.7)$$

where f^{abc} are the structure constants of $\text{SU}(3)_C$. The non-Abelian structure of the $\text{SU}(3)_C$ group allows for 3-gluon and 4-gluon interactions in addition to the quark-antiquark-gluon interactions.

The last term in Equation 1.5 violates CP conservation and produces a non-zero electric dipole moment (EDM) for the neutron. Experimental limits on the neutron EDM constraint the QCD vacuum angle θ to be smaller than 10^{-10} . The Peccei-Quinn theory provides a possible method to force θ to zero by introducing the hypothetical axion particle. The axion is a potential dark matter candidate and will be discussed further in Section 1.2.

1.1.2 Hadrons

Free quarks and gluons are not observed in nature, only in bound states called hadrons. This is a consequence of two factors: color confinement and asymptotic freedom.

Color confinement is the hypothesis that colored objects are always confined to color singlet states and that no objects with non-zero color charge can propagate as free particles. Thus, quarks can only exist in bound states of a quark-antiquark pair or three quarks, called mesons and baryons, respectively. Since gluons carry a color charge, they are confined to hadrons as well. Confinement is a low-energy non-perturbative phenomenon, occurring only below the QCD confinement scale Λ_{QCD} . An analytic proof of color confinement does not exist currently; however, the running of the strong coupling constant $\alpha_s = g_s^2/4\pi$ provides a mechanism for it.

Due to higher-order corrections to propagators in a QFT, physical quantities such as coupling constants and masses acquire a scale-dependence, where the value of the quantity changes as a function of the probed energy scale q^2 . The process of recovering scale-invariance is called renormalization and ensures that any divergent terms from the higher-order corrections cancel out in the physical values. Given the value of an arbitrary coupling constant α at some known scale μ^2 , the value of α at arbitrary scale q^2 is

$$\alpha(q^2) = \frac{\alpha(\mu^2)}{1 - \alpha(\mu^2) [\Pi(q^2) - \Pi(\mu^2)]}, \quad (1.8)$$

where $\Pi(q^2)$ and $\Pi(\mu^2)$ are the self-energy correction of the propagator at scales q^2 and μ^2 . While these individual terms are separately divergent, their difference is finite and calculable.

For values of q^2 and μ^2 larger than the confinement scale Λ_{QCD} , the difference between the gluon self-energy corrections to one-loop order is given by

$$\Pi_s(q^2) - \Pi_s(\mu^2) \approx -\frac{\beta}{4\pi} \ln \left(\frac{q^2}{\mu^2} \right) \quad (1.9)$$

where β depends on the number of quark and gluon loops. For N_c colors and N_f

quark flavors with mass below $|q|$,

$$\beta = \frac{11N_c - 2N_f}{12\pi}. \quad (1.10)$$

In the Standard Model, $N_c = 3$ and $N_f \leq 6$ regardless of energy, thus β is always positive. Combining Equations 1.8 and 1.9, the evolution of α_s is given by

$$\alpha_s(q^2) = \frac{\alpha_s(\mu^2)}{1 + \beta\alpha_s(\mu^2) \ln\left(\frac{q^2}{\mu^2}\right)} \approx \frac{1}{\beta \ln\left(\frac{q^2}{\Lambda_{\text{QCD}}^2}\right)} \quad (1.11)$$

for a sufficiently large energy scale $q^2 \gg \Lambda_{\text{QCD}}^2$. Through electron-positron collisions, the value of α_s at the Z -pole has been measured to be $\alpha_s(m_Z^2) = 0.1181 \pm 0.0011$ with a corresponding confinement scale of $\Lambda_{\text{QCD}} = 218 \text{ MeV}$.

From Equation 1.11, we see that α_s decreases with increasing q^2 . At $|q| \sim 1 \text{ GeV}$, the value of α_s is of $\mathcal{O}(1)$ confining quarks and gluons to hadrons in a strongly-bound non-perturbative state. However, $|q| \gtrsim 100 \text{ GeV}$, we have $\alpha_s \approx 0.1$ which is small enough that perturbation theory can be used and quarks can be treated as quasi-free particles. This property of QCD is known as asymptotic freedom.

1.1.3 Electroweak Interactions

The electroweak interactions of fermions are described by $\text{SU}(2)_L \times \text{U}(1)_Y$ gauge group, with the Lagrangian

$$\mathcal{L}_{\text{EWK}} = i\bar{\psi}_i \not{D} \psi_i - \frac{1}{4} \vec{W}_{\mu\nu} \cdot \vec{W}^{\mu\nu} - \frac{1}{4} B_{\mu\nu} B^{\mu\nu} \quad (1.12)$$

where repeated indices are contracted and $\psi \supseteq \{q_L, u_R, d_R, \ell_L, e_R, \nu_R\}$ is the set of SM fermions, and the gauge field tensors are given by

$$\begin{aligned} B_{\mu\nu} &= \partial_\mu B_\nu - \partial_\nu B_\mu \quad \text{and} \\ \vec{W}_{\mu\nu} &= \partial_\mu \vec{W}_\nu - \partial_\nu \vec{W}_\mu + g \vec{W}^\mu \times \vec{W}^\nu, \end{aligned} \quad (1.13)$$

where \vec{W}_μ and B_μ are the gauge fields for $SU(2)_L$ and $U(1)_Y$, respectively, and g is the coupling strength for $SU(2)_L$. The first term in Equation 1.12 contains the EWK covariant derivative

$$D_\mu = \partial_\mu - ig\vec{T} \cdot \vec{W}_\mu - ig'YB_\mu, \quad (1.14)$$

where g' is the coupling strength for $U(1)_Y$, Y is the $U(1)_Y$ hypercharge of the fermion field, and \vec{T} are the generators of the doublet representation of $SU(2)_L$. The generators can be written in terms of the Pauli spin matrices $\vec{T} = \vec{\sigma}/2$ and only have non-zero action on left-handed particles. The values of the hypercharge Y shown in Table 1.1 are chosen such that the physical electric charge of each fermion is given by $Q = T_3 + Y$.

Notice that Equation 1.12 does not contain a Dirac mass term like that found in Equation 1.5. This is because the term

$$m\bar{\psi}\psi = m(\bar{\psi}_L\psi_R + \bar{\psi}_R\psi_L) \quad (1.15)$$

mixes the left-handed and right-handed fermions leading to a Lagrangian that is no longer invariant under $SU(2)_L$. As the observed fermions are not massless, the Lagrangian given in Equation 1.12 is incomplete and an additional mechanism needs to be introduced to produce non-zero fermion masses.

1.1.4 Electroweak Symmetry Breaking

Spontaneous electroweak symmetry breaking provides the mechanism we need, as well as providing masses to the weak gauge bosons. The $SU(2)_L$ symmetry is broken by introducing a left-handed complex scalar doublet ϕ with $Y_\phi = 1/2$ to the Lagrangian in the following manner

$$\mathcal{L}_{\text{EWK}} \mapsto \mathcal{L}_{\text{EWK}} + |D_\mu\phi|^2 + \mu^2\phi^2 - \lambda|\phi|^4. \quad (1.16)$$

We choose to write this complex doublet, known as the complex Higgs field, in terms of four real-valued fields so that

$$\phi = \frac{1}{\sqrt{2}} \begin{pmatrix} \phi_1 + i\phi_2 \\ \phi_3 + i\phi_4 \end{pmatrix}. \quad (1.17)$$

Fortunately, the two self-interaction terms create a Higgs potential with a degenerate global minimum at the vacuum expectation value (vev)

$$v \equiv \langle |\phi| \rangle = \sqrt{\frac{\mu^2}{\lambda}}, \quad (1.18)$$

and through gauge rotations we set $\langle \phi_{1,2,4} \rangle = 0$, removing three degrees of freedom and producing three massless Nambu-Goldstone bosons. The remaining degree of freedom is the real Higgs field H which expresses small perturbations around the vev in the third component of the complex Higgs field $\phi_3 = v + H$.

The kinetic term in Equation 1.16 couples the complex Higgs field to the EWK gauge bosons as follows at the vev

$$|D_\mu \phi|^2 = \frac{v^2}{8} \left[(gW_\mu^1)^2 + (gW_\mu^2)^2 + (g'B_\mu - gW_\mu^3)^2 \right]. \quad (1.19)$$

Diagonalizing this term gives rise to the three massive weak bosons and the massless photon that we observe in nature:

$$\begin{array}{l|l} W_\mu^\pm \equiv \frac{1}{\sqrt{2}} (W_\mu^1 \mp W_\mu^2) & m_W = \frac{1}{2}vg \\ Z_\mu \equiv \cos \theta_W W_\mu^3 - \sin \theta_W B_\mu & m_Z = \frac{1}{2}v\sqrt{g^2 + (g')^2} \\ A_\mu \equiv \sin \theta_W W_\mu^3 + \cos \theta_W B_\mu & m_A = 0, \end{array} \quad (1.20)$$

where $\tan \theta_W = g'/g$. With this, we rewrite Equation 1.12 in terms of the observed

electromagnetic, charged weak, and neutral weak currents as follows:

$$\begin{aligned}\mathcal{L}_{\text{EWK}} = & \bar{\psi}_i (i\not{\partial} - eQ\not{A}) \psi_i - \frac{g}{2\sqrt{2}} \bar{\psi}_i (T^+ \not{W}^+ + T^- \not{W}^-) \psi_i - \frac{1}{2} m_W^2 W_\mu^+ W^{-\mu} \\ & - \frac{g}{2 \cos \theta_W} \bar{\psi}_i (g_V - g_A \gamma^5) \not{Z} \psi_i - \frac{1}{2} m_Z^2 Z_\mu Z^\mu, \quad (1.21)\end{aligned}$$

where $e = g' \cos \theta_W$ is the charge of the electron, $T^\pm = (T_1 \mp iT_2)/\sqrt{2}$ are the weak isospin raising and lowering operators, and $g_V = T_3$ and $g_A = T_3 - 2Q \sin^2 \theta_W$ are the vector and axial-vector couplings for the neutral weak current.

We can also expand Equation 1.16 about the vev giving us the following Higgs Lagrangian

$$\begin{aligned}\mathcal{L}_H = & \frac{1}{2} \partial_\mu H \partial^\mu H - \frac{1}{2} m_H^2 H^2 + \frac{m_H^2}{2v} H^3 + \frac{2m_W^2}{v} W_\mu^+ W^{-\mu} H + \frac{m_Z^2}{v} Z_\mu Z^\mu H \\ & + \frac{m_H^2}{8v^2} H^4 + \frac{m_W^2}{v^2} W_\mu^+ W^{-\mu} H^2 + \frac{m_Z^2}{2v^2} Z_\mu Z^\mu H^2, \quad (1.22)\end{aligned}$$

where $m_H = \mu\sqrt{2}$. Thus, we see that the real Higgs field H has trilinear and quartic couplings to itself and the weak gauge bosons with coupling strengths proportional to the mass squared of the appropriate boson. This suggests a way to introduce fermion masses through the Higgs field.

1.1.5 Fermion Masses

Introducing Yukawa couplings between the complex Higgs field ϕ and the SM fermion fields enables us to add mass terms for the fermions. First, we start with the terms for charged leptons,

$$\mathcal{L}_Y^{\text{leptons}} = -\bar{\ell}_L Y_e \phi e_R - \bar{e}_R Y_e \phi^\dagger \ell_L, \quad (1.23)$$

where Y_e is the Yukawa matrix for the charged leptons. In general, Yukawa matrices and thus mass matrices are non-diagonal and hence we need to convert from the electroweak eigenstates $f_{L,R}$ to the mass eigenstates $\tilde{f}_{L,R} = U_{L,R}^f f_{L,R}$ where $U_{L,R}^f$ is a

unitary matrix. With this we rewrite Equation 1.23 in terms of the mass eigenstates

$$\begin{aligned}\mathcal{L}_Y^{\text{leptons}} &= -\tilde{\ell}_L U_L^e Y_e \phi U_R^{e\dagger} \tilde{e}_R - \tilde{e}_R U_R^e Y_e \phi^\dagger U_L^{e\dagger} \tilde{\ell}_L \\ &= -\tilde{\ell}_L \tilde{Y}_e \phi \tilde{e}_R - \tilde{e}_R \tilde{Y}_e^\dagger \phi^\dagger \tilde{\ell}_L,\end{aligned}\tag{1.24}$$

where $\tilde{Y}_e = U_L^e Y_e U_R^{e\dagger}$ is the diagonalized Yukawa matrix for the charged leptons. After electroweak symmetry breaking, these terms become

$$\begin{aligned}\mathcal{L}_Y^{\text{leptons}} &= -\frac{v+H}{\sqrt{2}} \left(\tilde{e}_L \tilde{Y}_e \tilde{e}_R + \tilde{e}_R \tilde{Y}_e^\dagger \tilde{e}_L \right) \\ &= -\left(1 + \frac{H}{v} \right) \left(\tilde{e}_L \tilde{M}_e \tilde{e}_R + \tilde{e}_R \tilde{M}_e^\dagger \tilde{e}_L \right) \\ &= -\tilde{M}_e \bar{e} e - \frac{\tilde{M}_e}{v} \bar{e} e H,\end{aligned}\tag{1.25}$$

where $\tilde{M}_e = v \tilde{Y}_e / \sqrt{2}$ is the diagonalized mass matrix for the charged leptons and e is the set of massive Dirac spinors for the charged leptons.

From Equation 1.25, we see that the Yukawa couplings between the complex Higgs field ϕ and the charged leptons result in a Dirac mass term and a coupling to the real Higgs field H that is proportional to the mass of the charged leptons and the vev. The same procedure is used to introduce mass terms for the down-type quarks whereas for the neutrinos and up-type quarks we must use the conjugate doublet $\phi_c = -i\sigma_2 \phi^*$ in place of ϕ to obtain the same result.

1.1.6 Flavor Mixing

For the charged leptons and up-type quarks, it is possible to define a basis of simultaneous electroweak and mass eigenstates, so in practice $\tilde{Y}_{e,u} = Y_{e,u}$ as $U_L^{e,u} = U_R^{e,u} = \mathbf{I}$. However, it is not possible to do this for the neutrinos at the same time as the charged leptons or for the down-type quarks at the same time as the up-type quarks.

In Equation 1.21, the charged current term involves interactions between the up-type and down-type quarks and is not preserved under the transform $f \rightarrow \tilde{f}$. Writing

this in terms of the mass eigenstates we have

$$\begin{aligned}\mathcal{L}_{\text{CC}} &= -\frac{g}{2\sqrt{2}} \left(\bar{u}_L T^+ \mathcal{W}^+ d_L + \bar{d}_L T^- \mathcal{W}^- u_L \right) \\ &= -\frac{g}{2\sqrt{2}} \left(\bar{u}_L T^+ \mathcal{W}^+ V_{\text{CKM}} \tilde{d}_L + \bar{\tilde{d}}_L T^- \mathcal{W}^- V_{\text{CKM}}^\dagger u_L \right),\end{aligned}\quad (1.26)$$

where $V_{\text{CKM}} = U_L^{u\dagger} U_L^d$ is the Cabibbo-Kaboyshi-Maskawa matrix and $u_L = \tilde{u}_L$ by construction. The CKM matrix is unitary with four free parameters, the mixing angles between quark generations $\phi_{12} = 13.1$, ϕ_{23} , and ϕ_{13} as well as a CP-violating phase δ . In terms of these parameters, the CKM matrix is

$$V_{\text{CKM}} = \begin{pmatrix} c_{12} & s_{12} & 0 \\ -s_{12} & c_{12} & 0 \\ 0 & 0 & 1 \end{pmatrix} \times \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_{23} & s_{23} \\ 0 & -s_{23} & c_{23} \end{pmatrix} \times \begin{pmatrix} c_{13} & 0 & s_{13}e^{-i\delta} \\ 0 & 1 & 0 \\ -s_{13}e^{i\delta} & 0 & c_{13} \end{pmatrix}, \quad (1.27)$$

where $s_{ij} = \sin \phi_{ij}$ and $c_{ij} = \cos \phi_{ij}$. It has been experimentally determined that the CKM is mostly diagonal with $s_{13} \ll s_{23} \ll s_{12} \ll 1$.

The equivalent mixing matrix for the neutrinos is the Pontecorvo-Maki-Nakagawa-Sakata matrix U_{PMNS} , which converts from the mass eigenstates ν_1 , ν_2 , and ν_3 to the electroweak eigenstates ν_e , ν_μ , ν_τ . Unlike the CKM matrix, the PMNS is non-diagonal resulting in stronger mixing in the neutrino sector. The values of the mixing angles θ_{12} , θ_{23} , and θ_{13} have been measured in neutrino oscillation experiments while the CP-violating phase δ' has not yet been directly measured. From cosmological measurements, it is known that the sum of the neutrino masses is less than one eV.

1.1.7 Summary

The Standard Model has a total of 26 free parameters and 17 physical particles. The parameters are the twelve Yukawa couplings for the fermions, the four parameters of the CKM matrix, the four parameters of the PMNS matrix, the three coupling constants g_s , g , and g' , the Higgs vacuum expectation value v , the Higgs mass m_H , and the QCD vacuum angle θ . The best fit values of the SM parameters, excluding

Table 1.2: The free parameters of the Standard Model, not including masses.

| Parameter | Description | Best Fit Value |
|----------------------|--------------------------------|----------------|
| ϕ_{12} | CKM 12-mixing angle | 13.1° |
| ϕ_{23} | CKM 23-mixing angle | 2.4° |
| ϕ_{13} | CKM 13-mixing angle | 0.4° |
| δ | CKM CP-violating phase | 0.995 |
| $\sin^2 \theta_{12}$ | PMNS 12-mixing angle | 0.297 |
| $\sin^2 \theta_{23}$ | PMNS 23-mixing angle | 0.437 |
| $\sin^2 \theta_{13}$ | PMNS 13-mixing angle | 0.0214 |
| δ' | PMNS CP-violating phase | 1.35 |
| g_s | $SU(3)_C$ coupling constant | 1.221 |
| g | $SU(2)_L$ coupling constant | 0.652 |
| g' | $U(1)_Y$ coupling constant | 0.357 |
| v | Higgs vacuum expectation value | 246 GeV |
| θ | QCD vacuum angle | $< 10^{-10}$ |

masses, are summarized in Table 1.2.

The physical particles are the single-particle states of the various mass eigenfields and their properties are summarized in Table 1.3. Each of the fermion fields has a corresponding anti-particle with the electromagnetic and color charges inverted. Most of these single-particle states have finite lifetimes and decay to lower energy configurations. The only particles whose decays have not been observed are the photon, the electron, the neutrinos, and the proton (a baryon of flavor content uud). Additionally, stable bound states of protons and neutrons (a baryon of flavor content udd) exist in the form of atomic nuclei.

Table 1.3: The physical particles of the Standard Model.

| Name | Symbol | Spin | Charge | Mass |
|-------------------|------------|---------------|----------------|----------|
| up quark | u | $\frac{1}{2}$ | $\frac{2}{3}$ | 2.2 MeV |
| down quark | d | $\frac{1}{2}$ | $-\frac{1}{3}$ | 4.7 MeV |
| charm quark | c | $\frac{1}{2}$ | $\frac{2}{3}$ | 1.28 GeV |
| strange quark | s | $\frac{1}{2}$ | $-\frac{1}{3}$ | 95 MeV |
| top quark | t | $\frac{1}{2}$ | $\frac{2}{3}$ | 173 GeV |
| bottom quark | b | $\frac{1}{2}$ | $-\frac{1}{3}$ | 4.18 GeV |
| electron neutrino | ν_e | $\frac{1}{2}$ | 0 | - |
| electron | e | $\frac{1}{2}$ | -1 | 511 keV |
| muon neutrino | ν_μ | $\frac{1}{2}$ | 0 | - |
| muon | μ | $\frac{1}{2}$ | -1 | 105 MeV |
| tau neutrino | ν_τ | $\frac{1}{2}$ | 0 | - |
| tau | τ | $\frac{1}{2}$ | -1 | 1.78 GeV |
| gluon | g | 1 | 0 | 0 |
| photon | γ | 1 | 0 | 0 |
| Z boson | Z | 1 | 0 | 91.2 GeV |
| W boson | W^\pm | 1 | ± 1 | 80.4 GeV |
| Higgs boson | H | 0 | 0 | 125 GeV |

1.2 Dark Matter

As a theory of the fundamental particles and forces of nature, the Standard Model should also help explain physics at the largest scales. The Λ CDM model best explains all current cosmological observations including the structure of the cosmic microwave background; the abundances of hydrogen, helium, and lithium; the large-scale structure in the distribution of galaxies, and the accelerating expansion of the universe. However, the latest results from the Planck collaboration show that baryonic matter (matter consisting of combinations of protons, neutrons, and electrons) only contributes $\sim 5\%$ of the total energy of the universe, with radiation (photons and relativistic neutrinos) contributing less than a hundredth of a percent.

The remaining 95% of energy comes from just two sources: $\sim 27\%$ from non-relativistic non-baryonic matter referred to as dark matter and $\sim 68\%$ from an unknown form of energy that permeates all of space referred to as dark energy. Current observations show the latter is uniform in space and time producing a similar effect to that of the cosmological constant in the Einstein field equations of general relativity.

ity, sufficient explanation for the work shown in this thesis which shall focus on the former.

Dark matter cannot be explained by the 17 particles of the Standard Model, yet its gravitational effects have been observed in many circumstances. The rest of this section will cover the astrophysical evidence for dark matter (Section 1.2.1), various dark matter candidates (Section 1.2.2), and non-collider searches for dark matter (Section 1.2.3) before concluding with a discussion of the dark matter models investigated in this thesis (Section 1.2.4).

1.2.1 Astrophysical Evidence

All existing evidence for dark matter comes from astrophysical observations of its gravitational effects on the universe at various length scales. We shall focus on four different sources of evidence: the average velocity of galaxies in clusters, the rotation curves of spiral galaxies, strong gravitational lensing, and merging galactic clusters. The evidence presented here is not exhaustive, see Reference ?? for more detail.

Galactic clusters are the largest gravitational bound systems, with the orbital velocities of the individual clusters determined by the total gravitational mass of the cluster. Applying the Virial Theorem gives the explicit relation

$$v^2 = \frac{GM}{2r}, \tag{1.28}$$

where v is the average orbital velocity of a galaxy in the cluster, r is the average separation between galaxies in the cluster, M is the total gravitational mass of the cluster, and G is the Newtonian constant of gravitation. In 1933, Fritz Zwicky measured the average orbital velocity of the Coma cluster and discovered that it was a factor of ten larger than the observed visible mass of the Coma cluster, leading to the conclusion that the majority of the cluster consisted of non-luminous matter. Today studies show that stars only contribute 1% of the total cluster mass, with a hot, baryonic intracluster medium and dark matter contributing the remaining 14% and 85% of the total cluster mass, respectively.

Spiral galaxies are stable gravitational bound systems with stars and interstellar gas rotating around the galactic center in nearly circular orbits in a single plane. For these galaxies, the orbit of an individual star is stable when the gravitational force acting on the star balances the centripetal acceleration of the star. With this condition, the expected stellar velocity v is a function of distance r from the galactic center given by

$$v = \sqrt{\frac{GM(r)}{r}} \quad (1.29)$$

where $M(r)$ is the total gravitational mass inside radius r . Thus, past a certain critical radius r_c , the stellar velocity should fall with as $r^{1/2}$ as the mass of the galaxy is no longer increasing.

In 1980, Vera Rubin and Kent Ford observed that instead of decreasing at distances outside the visible galaxy, the stellar velocity stayed constant out to a very great distance, necessitating an additional non-luminous source of mass. The most common explanation for this missing mass is the existence of an isotropic dark matter halo surrounding the galaxy. With the inclusion of interstellar gas, the total mass inside radius r is given by

$$M(r) = 4\pi \int_0^r dr' (r')^2 \left[\rho_S(r') + \rho_g(r') + \rho_{DM}(r') \right], \quad (1.30)$$

where ρ_S , ρ_g , and ρ_{DM} are the density profiles of the stars, interstellar gas, and dark matter in the galaxy, respectively. Once these densities have been specified, it is possible to plot the fraction of the total stellar velocity for each mass source as a function of distance from the galactic center.

Figure 1-1 shows the results of doing this using the observed stellar and interstellar mass density profiles and the expected density from an isotropic dark matter halo for two different spiral galaxies. In both cases, this reproduces the observed flat galactic rotation curve incredibly well, lending strong support for the existence of galactic dark matter halos.

As a consequence of Einstein's equivalence principle, a massive body will deflect light, a phenomenon known as gravitational lensing. In the language of general rela-

Figure 1-1: The observed (points) and fitted (solid line) rotation curves for two sample galaxies. The fit consists of three components: the stellar component (dashed), the interstellar gas (dotted), and the dark matter halo (dash-dotted). Reprinted from Reference [1].

tivity, this means that the photons take the path given by the geodesic lines following the curvature of space-time due to the massive body. For most observations of gravitational lensing due to astrophysical bodies, the physical size of the lensing object is much smaller than the distance between observer, lens, and source allowing us to use the thin lens approximation. Approximating the lens as a planar distribution of matter, the angular deflection is given by

$$\vec{\alpha}(\vec{x}) = \frac{4G}{c^2} \int d^2x' \frac{\vec{x} - \vec{x}'}{|\vec{x} - \vec{x}'|^2} \int dz \rho(\vec{x}', z) \quad (1.31)$$

where \vec{x} is a two-dimensional vector in the plane of the lens, z is the perpendicular distance from the plane of the lens, and ρ is the three dimensional density. If the source is treated as a point mass, this reduces to

$$\alpha = \frac{4G}{c^2} \cdot \frac{M}{b} \quad (1.32)$$

where $b = |\vec{x} - \vec{x}'|$ is the impact parameter and M is the total mass of the object. Thus, measuring the angle of deflection due to gravitational lensing around an astrophysical object provides an independent measurement of the total mass of the body which can be compared against the mass of the luminous objects in the body.

Figure 1-2: Strong gravitational lensing around galaxy cluster CL0024+17, consisting of the gravitationally bound yellow, elliptical galaxies. The elongated blue objects are from much more distant galaxies behind the cluster which are distorted into arcs due to gravitational lensing from the dark matter halo surrounding the cluster. Depending on the mass of the deflecting body and impact parameter, the size of deflection can fall into three different regimes. The first of these is called strong lensing where the curving of space-time is so strong that light can travel multiple paths around the lens and still reach the observer. If the source is directly behind a circular lens, light travels around all sides of the lens and appears as an Einstein ring, while if the source is offset or the lens is non-circular, the source will instead appear in multiple locations as if viewed from slightly different angles. An example of strong lensing is shown in Figure 1-2.

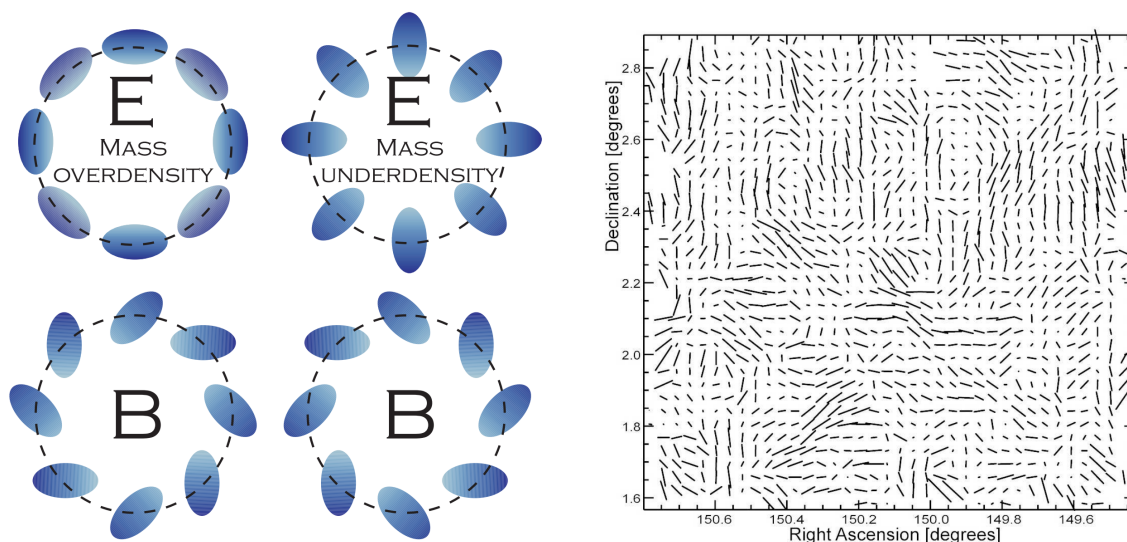

Figure 1-3: Left: Examples of circular “ E -mode” and curl-like “ B -mode” patterns. Right: The observed ellipticities of half a million distant galaxies within the 2 square degree Hubble Space Telescope COSMOS survey. Reprinted from Reference [1].

The next regime is known as weak lensing, where the deflection is enough to distort the image of the source but not enough to result in multiple images. The shear of this distortion can be converted into a map of the projected mass distribution. True weak lensing results in circular “ E -mode” patterns while sources of systematic uncertainty produce “ E -mode” and curl-like “ B -mode” patterns. Thus, requiring a zero “ B -mode” contribution assures that the measured mass distribution is accurate. Figure 1-3 shows the observed shear of half a million galaxies measured in the Hubble Space Telescope COSMOS survey.

The final regime is the microlensing that occurs when a lens moves relative to a luminous source. As the lens passes in front of the source, it will temporarily increase the apparent luminosity of the source, enabling a mass measurement of the lens. Microlensing results show that rocky exoplanets orbit other stars and that these planets cannot form the bulk of dark matter in the Milky Way.

Figure 1-4: The merging cluster 1E0657-558. The green contours show the weak lensing reconstruction of the gravitational potential of the cluster. The colors indicate the X-ray temperature of the plasma, changing from blue to white as the plasma goes from coolest to hottest. The smaller “bullet” cluster on the right which traversed through the larger cluster on the left. Reprinted from Reference [1].

Additionally, gravitational lensing measurements of galactic cluster collisions provide support for dark matter and help constrain its properties. Figure 1-4 shows the merging cluster 1E0657-558. By comparing the weak lensing reconstruction of the gravitational potential of the cluster shown in green contours against temperature color gradient of the X-ray emitting interstellar plasma, it was learned that the gravitational potential of the cluster doesn’t track the dominant baryonic mass contribution coming from the plasma. Instead, the gravitational potential tracks the smaller stellar baryonic mass component. Dark matter must be the dominant gravitational source in the cluster since the center of total mass is offset from the center of baryonic mass. Furthermore, the observation of two gravitational mass centers places

strong constraints on the self-interaction of dark matter requiring that the observed mass must have a self-interaction collisional cross section $\sigma/m < 1.25 \text{ cm}^2\text{g}^{-1}$ at a 68% confidence level.

1.2.2 Dark Matter Candidates

WIMPs and axions for now.

1.2.3 Non-collider Searches

Describes.

1.2.4 Simplified Models for LHC

It was the hot thing at the time.
